Stock Annex: Cod (*Gadus morhua*) in Subdivision 5.b.1 (Faroe Plateau)

Stock specific documentation of standard assessment procedures used by ICES.

**Stock:** Faroe Plateau cod (Division Vb1)

**Working Group:** North-Western Working Group

**Last updated:** May 2016

**Last updated by:** Petur Steingrund, Lise H. Ofstad

**A. General**

**A.1. Stock definition.**

Extensive tagging experiments on the Faroe Plateau (Strubberg, 1916; 1933; Tåning, 1940; Joensen *et al*., 2005; unpublished data) during a century strongly suggest that the cod stock on the Faroe Plateau is isolated from other cod stocks, e.g., from cod on the Faroe Bank and cod at Iceland. Only around 0.1% of recaptured tagged cod are recaptured in other areas than the Faroe Plateau (Joensen *et al*., 2005). The immigration rate from Iceland is even lower. During 1948–86, around 90 000 cod were tagged at Iceland and 11 000 recaptured. Of these, five cod were recaptured in Faroese waters and only three of them on the Faroe Plateau (Jónsson, 1996). Of cod tagged in the North Sea, one specimen has been recaptured at the Faroes (Bedford, 1966).

Icelandic and Faroese tagging experiments suggest that the cod population on the Faroe-Icelandic ridge mainly belongs to the Icelandic cod stock. Faroe Marine Research Institute tagged about 29 000 cod in Faroese waters during 1997–2009 and about 8 500 have been recaptured to March 2009. Of these, one individual was caught on the Icelandic shelf and one on the Faroe-Icelandic ridge. In 2002, 168 individuals were tagged on the Faroe-Icelandic Ridge (Midbank). Twelve have been recaptured so far, 6 at Iceland, 3 on the Faroe-Icelandic Ridge and 0 on the Faroe Plateau (3 had unknown recapture position). The Marine Research Institute in Iceland tagged 25 572 cod in Icelandic waters during 1997-2004 and 3 708 were recaptured to April 2006. Of these, only 13 individuals were recaptured on the Faroe-Icelandic ridge and none on the Faroe Plateau.

Genetic investigations indicate that Icelandic cod might be composed by two components (Pampoulie *et al*., 2006): a western component and an eastern component, which, genetically, is indistinguishable from the Faroe Plateau cod stock (Pampoulie *et al*., 2008). While Faroe Plateau cod is dominated by the Pan IA allele (above 0.8), the frequency is much lower (between 0.2–0.8) for Icelandic populations (Case *et al*., 2005), especially on the Faroe-Icelandic Ridge (0.2). The cod populations in the North Sea are dominated by the Pan IA allele (as the populations on the Faroe Plateau and the Faroe Bank) but they have a higher frequency of the HbI(1) hemoglobin allele (Sick, 1965). Hence, Faroe Plateau cod have a rather special combination of genetic traits, as they mainly possess the ‘coldwater’ hemoglobin allele (Hb-I(2)) and the ‘warmwater’ PanIA allele.
Cod spawn in February-March at two main spawning grounds north and west of the islands at depths around 90–120 m. The larvae hatch in April and are carried by the Faroe Shelf residual current (Hansen, 1992) that flows clockwise around the Faroe plateau within the 100–130 m isobath (Gaard et al. 1998; Larsen et al., 2002). The fry settle in July-August and occupy the near shore areas, which normally are covered by dense algae vegetation. In autumn the following year (i.e. as 1 group), the juvenile cod begin to migrate to deeper waters (usually within the 200 m contour), thus entering the feeding areas of adult cod. They seem to be fully recruited to the fishing grounds as 3 year olds. Faroe plateau cod mature as 3–4 year old. The spawning migration seems to start in January and ends in May. Cod move gradually to deeper waters when they are growing older. The diet in shallow water (< 200 m) is dominated by sandeels and benthic crustaceans, whereas the diet in deeper water mainly consists of Norway pout, blue whiting and a few species of benthic crustaceans. The food content of sandeels has been scarce since about 2003.

The geographical areas are presented in Figure 3.

A.2. Fishery

The cod fishery on the Faroe Plateau was dominated by British trawlers from 1898 to the 1960s. Faroese vessels took an increasing part of the share during the 1960s. In 1977, the EEZ was extended to 200 nautical miles, excluding most foreign fishing vessels from Faroese fishing grounds. In the 1980s, closed areas (mostly during the spawning time) were introduced and these were extended in the 1990s. Longliners and jiggers fished in shallow (< 150 m) waters, targeting cod and haddock, whereas trawlers exploited the deeper waters, targeting saithe. Small trawlers were allowed to exploit the shallow fishing grounds for flatfish during the summertime. After the collapse in the fishery in the beginning of the 1990s, which contributed to a serious national economic crisis in the Faroes, a quota system was introduced in 1994. It was in charge during 1994-1995, but was replaced by the effort management system in June 1996. The cod stock had by then recovered rapidly, which was in contrast with the scientific expectations.

A.3. Ecosystem aspects

The rapid recovery of the cod stock in the mid–1990s strongly indicated that ‘strange things’ had happened in the environment. It became clear that the productivity of the ecosystem affected both cod and haddock recruitment and growth (Gaard et al., 2002), a feature outlined in Steingrund and Gaard (2005). The primary production on the Faroe Shelf (< 130 m depth), which took place during May-June, varied interannually by a factor of five, giving rise to low- or high-productive periods of 2–5 years duration (Steingrund and Gaard, 2005). The productivity over the outer areas seems to be negatively correlated with the strength of the Subpolar Gyre (Hátún et al., 2005; Hátún et al., 2009; Steingrund et al., 2010), which may regulate the abundance of saithe in Faroese waters (Steingrund and Hátún, 2008). However, after around 2007 the positive link between the primary production and demersal fish has become less clear. The high primary production in 2008–2010 was not reflected in the productivity of cod and haddock although a little bit in the productivity of saithe. Also, the catchability with longlines after 2007 has increased by a factor of at least 2. In the same period the amount of zooplankton at the Faroes has been high as well as the abundance of mackerel and herring.
B. Data

B.1. Commercial catch

When calculating the catch-at-age, the sampling strategy is to have length, length-age, and length-weight samples from all major gears during three periods: January–April, May–August and September–December. In the period 1985–1995, the year was split into four periods: January–March, April–June, July–September, and October–December. The reason for changing from a four-period to a three-period split-up was that the three-period splitup was considered to be in better agreement with biological cycles (the spawning period ends in April). When sampling was insufficient, length-age and length-weight samples were borrowed from similar fleets in the same time period. Length measurements were, if possible, not borrowed. The number of samples in some years (e.g. 2005 and 2007–2008) was not sufficient to allow the traditional three period splitup for all the fleets, and a two period splitup (January–June and July–December) was adopted for those fleets. In recent years the two period splitup has been used.

The landing values were obtained from the Fisheries Ministry and Statistics Faroe Islands. The catches on the Faroe–Iceland ridge were not included in the catch-at-age calculations, a practice introduced in the 2005 WG. The catches on the Faroe-Iceland ridge were revised in 2016. Catch-at-age for the fleets covered by the sampling scheme were calculated from the age composition in each fleet category and raised by their respective landings. The catch-at-age by fleet was summed across all fleets and scaled to the correct catch.

Mean weight-at-age data were calculated using the length/weight relationship based on individual length/weight measurements of samples from the landings.

B.2. Biological

B.3. Surveys

The spring groundfish surveys in Faroese waters with the research vessel Magnus Heinason were initiated in 1983. Up to 1991 three cruises per year were conducted between February and the end of March, with 50 stations per cruise selected each year based on random stratified sampling (by depth) and on general knowledge of the distribution of fish in the area. In 1992 the period was shortened by dropping the first cruise and one third of the 1991-stations were used as fixed stations. Since 1993 all stations are fixed stations. The standard abundance estimates is the stratified mean catch per hour in numbers at age calculated using smoothed age/length keys. Mostly, the same strata (Strata 1 to 15) were used as in the summer survey and calculated in the same way (see below). However, five spawning strata are defined to reduce the influence of large hauls (Strata 16 to 20). In 2013 Strata 1 and 2 were merged (because of a large haul) giving a total number of 19 strata in the spring survey. The indices with 19 strata were updated for the entire period from 1994. All cod less than 25 cm were set to 1 year old.

In 1996, a summer (August-September) groundfish survey was initiated, having 200 fixed stations distributed within the 500 m contour of the Faroe Plateau. Half of the stations were the same as in the spring survey.
The abundance index was calculated as the stratified mean number of cod at age. The age length key was based on otolith samples pooled for all stations. Due to incomplete otolith samples for the youngest age groups, all cod less than 15 cm were considered being 0 years and between 15 and 34 cm 1 year (15-26 cm for 2005 because of abnormally small 2 year old fish). Since the age length key was the same for all strata, a mean length distribution was calculated by stratum and the overall length distribution was calculated as the mean length distribution for all strata weighted by stratum area. Having this length distribution and the age length key, the number of fish at age per station was calculated, and scaled up to 200 stations.

The proportion mature was obtained from the spring survey, where all aged individuals were pooled, i.e., from all stations, being in the spawning areas or not. The average maturity at age for 1983–1996 was used in years prior to 1983. Some of the 1983–1996 values were revised in 2003 but not the maturities for the 1961–1982 period.

B.4. Commercial CPUE

Three commercial cpue series (two for longliners and one for pair trawlers) are updated every year, but the WG decided in the benchmark assessment in 2004 not to use them in the tuning of the VPA. The cpue for the longliners was shown to be dependent upon environmental conditions whereas the cpue for the pair trawlers could in principle be influenced by other factors than stock size, for example the price differential between cod and saithe, although it has corresponded well with the survey indices. These three cpue series are presented in the report although they were not used as tuning series.

B.5. Other relevant data

C. Historical Stock Development

An XSA has been performed during a number of years. The use of tuning indices has, however, varied since the mid–1990s. The Faroese spring groundfish survey was excluded as a tuning series in the mid–1990s because the catch-curves in the survey showed an abnormal pattern. Two commercial tuning series (single trawlers 400–1000 HP and longliners > 100 GRT) were used during 1996–1998 where the effort was in number of days. In 1999, the tuning series constituted the pairtrawlers > 1000 HP (effort in the number of trawl hours) and the longliners > 100 GRT (effort in the number of hooks set). In 2002, the Faroese Summer Groundfish Survey was used as the only tuning series, as was the case in 2003. A benchmark assessment was performed in the 2004 NWWG, where the Faroese Spring Groundfish Survey was reintroduced, albeit with a modified stratification, i.e., the two surveys were used as the only tuning series. All assessments since then have been update assessments where only minor changes in settings have been made.

Model used: Extended Survivors Analysis.

Model Options chosen:

Time series weights: Tapered time weighting not applied. Catchability analysis: Catchability independent of stock size for all ages. Catchability independent of age for ages >= 6. Terminal population estimation: Survivor estimates shrunk towards the mean F
of the final 5 years or the 5 oldest ages. S.E. of the mean to which the estimates are shrunk = 2.00. Minimum standard error for population estimates derived from each fleet = 0.300. Prior weighting not applied.

D. Short-Term Projection

Model used: Age structured.

Software used: MFDP prediction with management option table and yield per recruit routines.

Initial stock size. Taken from XSA for all ages (2–10+).

Natural mortality: Set to 0.2 for all ages in all years.
Maturity: The values observed in the spring survey 2014 are used for 2014 while average maturities 2012–2014 are used in 2015 and 2016.

F and M before spawning: Set to 0 for all ages in all years.

Weight at age in the stock: The same values as weight-at-age in the catch.

Weight at age in the catch: For each age, a regression was performed between the weight-at-age during the whole year and 1) the weight-at-age during January-February or 2) the weight-at-age in the spring survey 1994–2014. The relationship with the higher coefficient of correlation was used as a basis to predict the weight-at-age in 2014. The values for 2015–2016 were set to the 2014 value.

Exploitation pattern: Average for the three last years when there is no trend in the series or rescaled to terminal year when there is a trend in the series.

Intermediate year assumptions: average for the three last years, i.e., not rescaled to the terminal year.

Stock recruitment model used: none.

Procedures used for splitting projected catches: none.

**E. Medium-Term Projections**
Not performed.

**F. Long-Term Projections**
Model used: Yield and biomass per recruit over a range of F-values.

Software used: MFYPR version 1.

Maturity: Average for 1983-last data year+1.

F and M before spawning: Set to 0 for all ages and years.

Weight at age in the stock: Same as the weights in the catch.

Weight at age in the catch: Average for 1978-last data year in order exclude the high values in former times.

Exploitation pattern: Average for 2000-last data year (not rescaled to the terminal year) in order to reflect a recent fishing pattern.

Procedures used for splitting projected catches: none.

A long-term simulation model is used, see text in the report.
G. Biological Reference Points

The reference points are dealt with in the general section of Faroese stocks. The reference points for Faroe Plateau cod are the following: $B_{pa} = 40\text{kton}, B_{lim} = 21\text{kton}, F_{pa} = 0.35$ and $F_{lim} = 0.68$.

H. Other Issues

I. References
